Pharmacogenetic Inhibition of eIF4E-Dependent Mmp9 mRNA Translation Reverses Fragile X Syndrome-like Phenotypes

Highlights

- P-eIF4E and MMP-9 expression is elevated in brains of FXS patients and Fmr1<sup>−/−</sup> mice
- MMP-9 overexpression engenders FXS-like phenotypes in mice
- Increased phosphorylation of eIF4E in Fmr1<sup>−/−</sup> mice promotes Mmp9 mRNA translation
- Genetic or pharmacological inhibition of p-eIF4E corrects ASD-like behaviors

In Brief

Fragile X syndrome (FXS) is caused by dysregulation of translation in the brain. Gkogkas et al. show that phosphorylation of eukaryotic translation initiation factor 4E (eIF4E) is increased in FXS postmortem brains and Fmr1<sup>−/−</sup> mice. Downregulation of eIF4E phosphorylation in Fmr1<sup>−/−</sup> mice rescues defects in dendritic spine morphology, synaptic plasticity, and social interaction via normalization of MMP-9 expression.
Pharmacogenetic Inhibition of eIF4E-Dependent Mmp9 mRNA Translation Reverses Fragile X Syndrome-like Phenotypes

SUMMARY

Fragile X syndrome (FXS) is the leading genetic cause of autism. Mutations in Fmr1 (fragile X mental retardation 1 gene) engender exaggerated translation resulting in dendritic spine dysmorphogenesis, synaptic plasticity alterations, and behavioral deficits in mice, which are reminiscent of FXS phenotypes. Using postmortem brains from FXS patients and Fmr1 knockout mice (Fmr1−/−), we show that phosphorylation of the mRNA 5′ cap binding protein, eukaryotic initiation factor 4E (eIF4E), is elevated concomitant with increased expression of matrix metalloproteinase 9 (MMP-9) protein. Genetic or pharmacological reduction of eIF4E phosphorylation rescued core behavioral deficits, synaptic plasticity alterations, and dendritic spine morphology defects via reducing exaggerated translation of Mmp9 mRNA in Fmr1−/−/y mice, whereas MMP-9 overexpression produced several FXS-like phenotypes. These results uncover a mechanism of regulation of synaptic function by translational control of Mmp-9 in FXS, which opens the possibility of new treatment avenues for the diverse neurological and psychiatric aspects of FXS.

INTRODUCTION

Autism spectrum disorders (ASDs) are identified by a cluster of symptoms in three core domains: social interaction, language, and range of interests, but in most cases their etiology is unknown (Elsabbagh et al., 2012). Fragile X syndrome (FXS) is characterized by core deficits in intellectual function, hyperarousal and anxiety, repetitive behaviors, and morphological abnormalities and has a known genetic cause. Many CGG repeats in the FMR1 gene induce its hypermethylation, transcriptional silencing, and loss of fragile X mental retardation protein (FMRP) expression (Verkerk et al., 1991; Hagerman and Hagerman, 2013). A large percentage of individuals with FXS (~46%) are co-diagnosed with ASD (Gudimirovic and Kaufmann, 2011). Importantly, FXS is the leading known genetic cause of autism. FMRP is a RNA-binding protein and binds to several ASD-linked mRNAs (Ascano et al., 2012; Darnell et al., 2011) and represses their translation (Darnell et al., 2011). According to the metabotropic glutamate receptor (mGluR) theory of FXS, loss of FMRP expression in FXS induces exaggerated translation of synaptic plasticity-related mRNAs, downstream of group I mGluR activation (Bear et al., 2004). This mechanism is best demonstrated in Fmr1−/− mice (Fmr1 deletion on the X chromosome), which display enhanced rates of translation, aberrant spine morphology (increased numbers of long, thin dendritic spines, which are typical of immature synapses and are also observed in FXS patients) (McKinney et al., 2005; Rudelli et al., 1985), defects in synaptic plasticity (enhanced protein synthesis-dependent mGluR long-term depression (LTD)) (Huber et al., 2001), and morphological/anatomical alterations reminiscent of FXS patients (macroorchidism) (The Dutch-Belgian Fragile X Consortium, 1994; Sutherland and Ashforth, 1979).

The translational inhibitory activity of FMRP is regulated primarily by two intracellular signaling cascades known to couple mGluRs to the translational machinery: the PI3K/Akt/mammalian target of rapamycin (mTOR) (Sharma et al., 2010) and the Ras/ERK (extracellular signal-regulated kinase)/Mnk (mitogen-activated protein kinase interacting kinases) (Osterweil et al., 2010). These pathways stimulate cap-dependent translation by...
controlling the phosphorylation of translation initiation factors. mTOR phosphorylates 4E-BPs (eukaryotic Initiation Factor 4E-Binding Proteins, which are inhibitors of elf4E) and S6Ks (ribosomal protein S6 Kinases) to promote translation initiation (Hay and Sonenberg, 2004). Genetic deletion of 4E-BP2 (Gkogkas et al., 2013) or overexpression of elf4E (Santini et al., 2013) engenders autism-like behaviors and synaptic plasticity deficits in mice. Genetic removal of S6K1 corrected molecular, synaptic, and behavioral deficits in Fmr1 y/C0 mice (Bhattacharya et al., 2012). Moreover, deletion of CPEB1 (cytoplasmic polyadenylation element binding protein 1), an activator of translation, induces phenotypes reminiscent of FXS. We demonstrate that translation of Mmp9 mRNA is increased due to elevated elf4E phosphorylation in Fmr1 y/C0 mice. Moreover, genetic reduction of phospho-elf4E rescues aberrant Mmp9 mRNA translation and reverses morphological, synaptic, and behavioral deficits in Fmr1 y/C0 mice. Pharmacological inhibition of elf4E phosphorylation by cercosporamide, a potent inhibitor of Mnk kinases (Konicek et al., 2011), reproduces the morphological, synaptic, and behavioral rescue in Fmr1 y/C0 mice. Thus, translational control of Mmp9 mRNA in response to Mnk-mediated phosphorylation of elf4E is a mechanism downstream of group 1 mGluRs, which is dysregulated in FXS (Figure S1).

RESULTS

Elevated Phosphorylation of elf4E and MMP-9 Protein Amounts in FXS Patients and Fmr1 y/C0 Mice

To investigate whether elf4E phosphorylation and MMP-9 expression are altered in FXS, we used postmortem brain samples from FXS patients and age-matched controls. Immunoblot analysis of frontal cortex and hippocampal samples from FXS patients using a phospho-elf4E (Ser 209) antibody revealed a 37.3% ± 2.8% increase in p-elf4E levels, accompanied by a 42.7% ± 3.2% increase in MMP-9 protein amounts, as compared to control individuals (Figures 1A and 1B; Figures S2A and S2B). The increase in p-elf4E and Mmp-9 protein amounts was recapitulated in Fmr1 y/C0 mice (Figures 1C and 1D); p-elf4E levels were increased by 67.1% ± 3.4% and Mmp-9 by 41.1% ± 4.1%, as compared to wild-type mice (Figures 1C and 1D). Using immunohistochemistry, we observed increased p-elf4E in the cortex, thalamus, and hippocampus of the Fmr1 y/C0 mice (Figures 1E and 1F; Figure S2C). Taken together, these data reveal increased elf4E phosphorylation and Mmp-9 protein amounts in the brains of FXS patients and Fmr1 y/C0 mice.

MMP-9 Overexpression Engenders Autism/FXS-like Phenotypes

Because Mmp-9 is linked to FXS and ASD (Bilousova et al., 2009), we asked whether MMP-9 overexpression would engender FXS-like phenotypes in mice. To this end, we used transgenic (Tg) mice expressing human pro-MMP-9 under the control of the PDGF-B promoter (Fragkouli et al., 2012), mimicking the increase of MMP-9 in FXS patients and Fmr1 y/C0 mice (Fragkouli et al., 2012; Figure 1). In MMP9-Tg mice, there is an increase in both the latent (pro-) and proteolytically activated forms of MMP-9 (Fragkouli et al., 2012), which is equivalent to the increase observed in Fmr1 y/C0 mice (Figures 1C and S2D). To assess whether MMP-9 overexpression causes social behavior deficits, as observed in the Fmr1 y/C0 mice, we subjected the MMP9-Tg mice to the three-chamber social interaction test (Silverman et al., 2010). Social approach behavior was impaired in MMP9-Tg mice, because they failed to show a preference for the social (stranger 1) versus the nonsocial stimulus (empty wire cage; p > 0.05, Figure 2A), as compared to wild-type littermates. As expected, MMP9-Tg mice were also impaired in the subsequent three-chamber preference for social novelty test.
Figure 1. Elevated Phosphorylation of eIF4E and Increased Expression of MMP-9 in Post-mortem Brains from FXS Patients and in Fmr1–/– Mouse Brain  
(A) Western blot analysis of lysates from frontal cortex or hippocampus from control “C” (n = 9) and FXS patients “FXS” (n = 8; see Figure S2). Representative images of immunoblots probed with antibodies against the indicated proteins are shown. HSC70 was the loading control.  
(B) Quantification of western blots from (A). Protein amounts of phospho-eIF4E and MMP9 are normalized to total eIF4E and HSC70 (n = 3 for each group) and presented as fold change relative to control.  
(C) Western blot analysis of whole-brain lysates from Fmr1–/– and wild-type (WT) littermates (n = 3 for each group). Representative images of immunoblots probed with antibodies against the indicated proteins are shown; β-tubulin was the loading control.  
(D) Quantification of data in (C) for phospho-eIF4E and Mmp9 protein amounts (n = 3 for each group), normalized to eIF4E and β-tubulin, respectively, and presented as fold change relative to WT.  
(E) Immunohistochemical DAB staining of cortical (CTX), hippocampal (HIPP), and thalamic (THAL) 50 μm slices from WT and Fmr1–/– mice. Representative images of slices stained with antibodies against the indicated proteins are shown.  
(F) Quantification of immunohistochemical staining in (E) for phospho-eIF4E (n = 3 for each group; fold change relative to WT). For (A)–(F), Student’s t test, *p < 0.05. See also Figure S2. Data are presented as mean ± SEM (error bars).

(Figure 2A). We then examined the MMP9-Tg mice for repetitive/stereotyped behaviors, which are a hallmark of FXS patients and Fmr1–/– mice (Bhattacharya et al., 2012), using the self-grooming test. MMP9-Tg mice spent significantly more time (106.8% ± 8.4%) grooming than their wild-type littermates, whereas no significant differences were observed in the duration of each grooming bout (Figure 2B).  

FXS patients have increased density of immature (filopodial type) dendritic spines (Rudelli et al., 1985). This phenotype is recapitulated in Fmr1–/– mice (McKinney et al., 2005). Using Golgi-Cox staining in MMP9-Tg mice, we found increased density of dendritic spines in CA1 hippocampal area (45.2% ± 4.1%), along with a decreased number of mature (54.3% ± 2.4%); stubby and mushroom type) and increased number of immature (57.8% ± 2.1%) spines, as compared to wild-type littermates (Figures 2C–2E). Macroorchidism is commonly diagnosed in FXS patients (Sutherland and Ashworth, 1979) and is also observed in Fmr1–/– mice (Bhattacharya et al., 2012). Testes from MMP9-Tg mice at postnatal days 90–100 weighed significantly more (55.4% ± 0.8%, Figure 2F), as compared to wild-type littermates. Taken together, these data demonstrate that overexpression of MMP-9 engenders phenotypes similar to those observed in Fmr1–/– mice, such as social deficits, repetitive/stereotyped behaviors, and abnormalities in dendritic spine morphology, indicating that increased MMP-9 protein amounts may substantially contribute to FXS pathophysiology.

Exaggerated Mmp9 mRNA Translation in Fmr1–/– Mice Is Alleviated by Genetic Inhibition of eIF4E Phosphorylation  
We hypothesized that exaggerated translation in Fmr1–/– mice could be rescued by genetically reducing eIF4E phosphorylation, which is a major effector of the hyperactivated Ras/MAPK/Mnk signaling pathway (Buxade et al., 2008). Importantly, Mmp9 mRNA is translationally controlled by FMRP at the synapse (Ascano et al., 2012; Darnell et al., 2011; Janusz et al., 2013). We reported that Mmp9 mRNA is translationally controlled by eIF4E phosphorylation in fibroblasts (Furic et al., 2010). Thus, we sought to investigate whether in the brain the translation of Mmp9 mRNA is regulated by eIF4E phosphorylation.

We crossed Fmr1–/– mice with Eif4ek1Δ/Δ (knockin; Ser209-Ala) mice (Eif4eΔΔ) or with the Mnk1–/–/Mnk2–/– heterozygote mice (Mnkhet) to generate “double-mutant” mice (Figure 3A). To assess the effect of the genetic reduction of eIF4E phosphorylation on protein synthesis, we measured de novo protein synthesis in hippocampal slices using puromycin labeling, to tag nascent polypeptide chains (Bhattacharya et al., 2012; Graber et al., 2013; Schmidt et al., 2009). Although we did not detect any significant changes in puromycin incorporation in Eif4eΔΔ and Mnkhet slices (Figure S3A), Fmr1–/– hippocampal slices incorporated significantly more puromycin (55.3% ± 6.9%), as compared to slices from wild-type mice (Figure 3B), indicating enhanced translation. Puromycin
incorporation was significantly reduced in both Fmr1−/−/Eif4eΔy and Fmr1−/−/Mnkhet slices, as compared to Fmr1−/− slices, thus demonstrating restoration of protein synthesis, as a result of the reduction in eIF4E phosphorylation (Figures 3B and 3C).

Next, we investigated the effect of reduction of eIF4E phosphorylation in Fmr1−/− mice on specific mRNAs. FMRP inhibits the translation of a subset of mRNAs (Ascano et al., 2012; Damell et al., 2011), either directly through binding to ribosome (Chen et al., 2014) or indirectly by regulating signaling downstream of group 1 mGluRs, impinging upon translation and transcription. We carried out polysome profiling of hippocampal lysates from the four different mouse genotypes examined for global protein synthesis (Figure 3B). No significant changes were detected between the different genotypes in the overall sedimentation profiles of hippocampal tissue (Figure 3D), albeit there was a trend for enhanced association of mRNAs with polysomes in the Fmr1−/− mice, when compared to the other genotypes, as evidenced by the Poly-somes/Monosome ratio (Figure S3B). Quantitative RT-PCR (qRT-PCR) analysis of the sucrose density gradient fractions revealed that in accordance with the data in fibroblasts (Furic et al., 2010), Mmp9 mRNA is associated with lighter polysome fractions in Eif4eΔy and Mnkhet mice, as compared to wild-type (WT) mice (Figures S3C and S3D), demonstrating that Mmp9 mRNA translation is promoted by eIF4E phosphorylation in the brain. Conversely, Mmp9 mRNA cosediments with heavier polysome fractions in Fmr1−/−, as compared to wild-type mice (Figure 3F), indicative of Mmp9 mRNA enhanced translation in the brain of Fmr1−/− mice. It is therefore predicted that in the ‘‘double-mutant’’ strains, Mmp9 mRNA translation would be restored to wild-type levels, as a result of reduced eIF4E phosphorylation. Indeed, in Fmr1−/−/Eif4eΔy and Fmr1−/−/Mnkhet mice, Mmp9 mRNA distribution is indistinguishable from wild-type mice (Figure 3F). This is also reflected in the amounts of Mmp9 (Figures 3G and 3H). Importantly, because we did not observe any changes in total Mmp9 mRNA amounts (Figure 3E) between the different genotypes, increased Mmp9 protein expression detected in Fmr1−/− mice (Figures 1C, 1D, 3G, and 3H) can be explained by increased translation of the Mmp9 mRNA.

Next, we asked whether translation of other known FMRP target mRNAs, whose expression is enhanced in Fmr1−/− mice, is also regulated via eIF4E phosphorylation. We observed reversal of the enhanced translation of mRNAs encoding additional members of the Mmp family: Mmp2, Mmp3, Mmp7, and Mmp24 and of Dlg4 (PSD-95) mRNAs (Figures S3D and S3E). Notably, decreased eIF4E phosphorylation had no effect on the translation of other known FMRP target mRNAs, such as Map1b, Shank1, Shank2, Shank3, Nrf2, and Camk2α (Figures S3D, S3F, and S3G). Taken together, these data demonstrate that genetic reduction of eIF4E phosphorylation negates the exaggerated translation of Mmp9 mRNA in Fmr1−/− mice by attenuating the hyperactivated Ras/MAPK/Mnk signaling, thus restoring normal rates of translation in Fmr1−/− mice.
Genetic Reduction of eIF4E Phosphorylation Reverses Aberrant Dendritic Spine Morphology, Excessive LTD, and FXS-like Behavioral Phenotypes in Fmr1−/− Mice

Having determined that MMP-9 overexpression in mice induces phenotypes that are commonly observed in Fmr1−/− mice (Figure 2), and that genetic reduction of eIF4E phosphorylation decreases translation of Mmp9 mRNA in Fmr1−/− mice (Figure 3), we investigated whether genetic reduction of eIF4E phosphorylation would rescue abnormalities in dendritic spine morphology, synaptic plasticity, and behavioral deficits in Fmr1−/− mice (Figure 4A). Using Golgi-Cox staining in hippocampal CA1 slices from the different mouse genotypes, we observed a decrease in the number of immature and an increase in the number of mature spines in both Fmr1−/−/Eif4Eki and Fmr1−/−/Mnkhet mice (Figure 4B).
mice, as compared to the Fmr1<sup>−/−</sup> mice (Figures 4B and 4C), which restores the dendritic spine phenotype to wild-type levels. On the other hand, we did not observe any significant changes in CA1 dendritic morphology in Elf4e<sup>ki</sup> or Mnk<sup>het</sup> mice, when compared to wild-type mice (Figure S4A).

Elevated translation in Fmr1<sup>−/−</sup> mice leads to enhanced hippocampal mGluR-LTD (Huber et al., 2001). Consistent with these findings, stimulation of group 1-metabotropic glutamate receptors led to enhanced mGluR-LTD in Fmr1<sup>−/−</sup> hippocampal slices (Figure 4D). In contrast, mGluR-LTD in hippocampal slices from Elf4e<sup>ki</sup> and Mnk<sup>het</sup> mice was not significantly different from that of wild-type mice (Figure S4B). Input/output curves and paired pulse ratio were also unaffected in Elf4e<sup>ki</sup> and Mnk<sup>het</sup>, as compared to wild-type mice (Figures S5A and S5B). In slices from Fmr1<sup>−/−</sup>/Elf4e<sup>ki</sup> and Fmr1<sup>−/−</sup>/Mnk<sup>het</sup> mice, mGluR-LTD was comparable to that from WT slices and significantly lower than in Fmr1<sup>−/−</sup> slices (Figures 4D and 4E).

Next, we explored the effects of Elf4E phosphorylation on FXS-like behaviors. We first subjected mice to the three-chamber preference for social novelty test. In agreement with previous reports (Bhattacharya et al., 2012), we noted an impaired preference for social novelty in the Fmr1<sup>−/−</sup> mice, whereas WT mice clearly show a preference for the novel social stimulus (stranger 2), as compared to the original social stimulus (stranger 1; Figure 4F). In the “double mutants,” reducing Elf4E phosphorylation rescued the impairment in the preference for social novelty test, as compared to Fmr1<sup>−/−</sup> mice (Figure 4F). To further investigate the reversal of the social behavior impairment, we carried out direct social interaction tests with a juvenile (Figure 4G) or a female mouse (Figure 4H). During the interaction with a juvenile male, Fmr1<sup>−/−</sup> mice displayed aggressive behavior (shorter latency to attack; Figure 4G), but not significant changes in social interaction (time in affiliation; Figure 4G), as compared to wild-type littermates. When an Fmr1<sup>−/−</sup> male interacted with a female mouse, it displayed repetitive behavior, engaging in increased duration of self-grooming, and demonstrated reduced male-female affiliation time (Figure 4H). These data are consistent with previous reports for Fmr1 knockout in the C57BL/6 background (Bhattacharya et al., 2012). In the “double mutants,” where Elf4E phosphorylation is reduced, there was a complete rescue of the aggressive behavior while interacting with a juvenile mouse (Figure 4G), partial rescue of the repetitive, excessive grooming, and complete rescue of the reduced affiliation while interacting with a female (Figure 4H), as compared to wild-type mice. Yet, in Elf4e<sup>ki</sup> and Mnk<sup>het</sup> mice, there were no significant behavioral changes in the direct social interaction tests with a juvenile male or a female (Figure S4D). Conversely, Elf4e<sup>ki</sup> and Mnk<sup>het</sup> mice display impaired preference for social novelty, as compared to wild-type mice (Figure S4C). This shows that the rescues are specific.

Hyperactivity, seizures, and epilepsy are common symptoms in FXS, which are also exhibited by Fmr1<sup>−/−</sup> mice (Musumeci et al., 2007; Spencer et al., 2005). To assess hyperactivity, we performed the light-dark transition (Figure 4I) and open-field tests (Figure 4J). Fmr1<sup>−/−</sup> mice are significantly more active than wild-type littermates as depicted by the number of light-dark compartment transitions (Figure 4I) and the number of entries and time spent in the center square of the open-field arena (Figure 4J). The “double mutants” showed reversal of hyperactivity/anxiety-like phenotypes in the light-dark and open-field tests (Figures 4I and 4J). We then proceeded to examine the effect of reduced Elf4E phosphorylation on audiogenic seizure susceptibility (AGS), which is age dependent (peak sensitivity at P21). C57Bl/6 mice are resistant to AGS (Seyfried et al., 1980). Fmr1<sup>−/−</sup> mice displayed increased tonic-clonic seizures, and respiratory arrest or death (Figure 4K). The “double mutants” were resistant to the induction of AGS, with only a small number of animals (~25%) displaying AGS. On the other hand, Elf4e<sup>ki</sup> and Mnk<sup>het</sup> mice behavior was comparable to wild-type animals in the light-dark, open-field, and AGS tests (Figures S4E; Elf4e<sup>ki</sup> and Mnk<sup>het</sup> mice were similar to wild-type). Because MMP-9 overexpression led to a macroorchidism phenotype, we examined whether inhibition of Elf4E phosphorylation (and thus reduced translation of Mmp9 mRNA) would rescue this FXS-like phenotype. Indeed, “double-mutant” mice display a significant decrease in testicular weight when compared to Fmr1<sup>−/−</sup> mice, which constitutes a complete rescue of the macroorchidism phenotype when compared to wild-type mice (Figure S4F). We did not observe any rescue in the novel object recognition or the rotarod (motor coordination) tests (Figures S4G and S4H). However, in these tests, Fmr1<sup>−/−</sup> mice displayed significant impairments in accordance with previous reports (Bhattacharya et al., 2012), whereas Elf4e<sup>ki</sup> and Mnk<sup>het</sup> mice performed similarly to wild-type (Figures S4G and S4H). Additionally, we confirmed that the rescue effect was not male specific because also in female Fmr1<sup>−/−</sup> mice genetic reduction of Elf4E phosphorylation corrected impaired preference for social novelty (Figure S2E). In summary, these findings demonstrate that genetic inhibition of Elf4E phosphorylation (which reduces translation of Mmp9 mRNA) is sufficient to reverse the aberrant dendritic spine morphology, synaptic mGluR-LTD deficits, and several core ASD-like phenotypes in Fmr1<sup>−/−</sup> mice.

**Chronic Pharmacological Inhibition of Elf4E Phosphorylation Reverses Excessive LTD and FXS-like Phenotypes in Fmr1<sup>−/−</sup> Mice**

Cercosporamide is a potent inhibitor of Mnk1/Mnk2 kinases (Koniczek et al., 2011) (Figure 5A). Cercosporamide has been tested in preclinical models of lung and colon carcinomas, where it substantially reduced proliferation and survival of cancer cells (Koniczek et al., 2011). We first studied the effects of cercosporamide on Elf4E phosphorylation in the brain. Following a single intraperitoneal injection of 20 mg/kg of cercosporamide in wild-type mice, we detected a decrease in Elf4E phosphorylation (~25%), whereas a dose of 40 mg/kg led to an ~50% decrease (Figure S5C). Mass spectrometry analysis of brain tissue revealed that cercosporamide was present in the brain, thus demonstrating that it crosses the blood-brain barrier (Figure S5D). To assess the effect of chronic cercosporamide treatment, we injected mice daily for 5 days with various concentrations of cercosporamide and subjected the mice to the threechamber social interaction test. The 40 mg/kg 5 day regimen impaired social approach behavior in WT mice, whereas the 20 mg/kg had no significant effect (Figure S5E). Importantly, the cercosporamide dose response experiment in Elf4e<sup>ki</sup> and
Mnk<sup>kat2</sup> mice revealed that social approach behavior for both genotypes was not affected by 40 mg/kg for 5 days, indicating that at these concentrations (20–40 mg/kg) the effect of cercosporamide is mediated specifically via eIF4E phosphorylation (Figure S5F). We thus used the 20 mg/kg 5 day treatment as “sub-threshold” and the 40 mg/kg as “above threshold.” Chronic treatment with “subthreshold” cercosporamide concentration reduces eIF4E phosphorylation and expression of Mmp-9 (Figures 5B and 5C).

Next, we tested whether pharmacological reduction of eIF4E phosphorylation using chronic cercosporamide treatment normalizes elevated general translation in Fmr1<sup>1/y</sup> mice. To this end, we prepared hippocampal slices from WT and in Fmr1<sup>1/y</sup> mice treated chronically with 20 mg/kg cercosporamide or vehicle and measured de novo protein synthesis using puromycin labeling. We detected a reversal by cercosporamide of the increase in puromycin incorporation in slices from Fmr1<sup>1/y</sup> mice, but no significant effect in slices from WT mice (Figure S5G).

Having established that cercosporamide crossed the blood-brain barrier and reduced eIF4E phosphorylation, we treated Fmr1<sup>1/y</sup> mice and wild-type littermates with the subthreshold dose of cercosporamide (20 mg/kg, 5 days; Figures 5A–5C). First, we measured dihydroxyphenylglycine (DHPG)-induced mGluR-LTD in CA1 hippocampal slices prepared from vehicle and cercosporamide-treated animals. Cercosporamide-treated Fmr1<sup>1/y</sup> mice displayed a significant decrease in mGluR-LTD (~20%; Figures 5D and 5E), in comparison to vehicle-treated Fmr1<sup>1/y</sup> mice, whereas in wild-type mice the mGluR-LTD was not affected by chronic cercosporamide treatment (Figures 5D and SE). One injection of cercosporamide (20 mg/kg) had no effect on DHPG-induced mGluR-LTD in Fmr1<sup>1/y</sup> mice (Figures S5H and S5I). Chronic cercosporamide treatment in Fmr1<sup>1/y</sup> mice achieved a complete reversal of several ASD-like behaviors, such as the preference for social novelty impairment (Figure 5F), without affecting social approach behavior in the three-chamber test (Figure S6A). The aggressive behavior toward a juvenile male (Figure 5G), the reduced sociability and the occurrence of repetitive behaviors (exaggerated self-grooming and reduced affiliation) during the interaction with a female (Figure 5H), the hyperactivity behavior, as illustrated by the increased number of light-dark transitions (Figure 5I) and centered-square occupancy in the open-field test (Figure 5J), and finally the increased susceptibility to AGS (Figure 5K). Similarly to the genetic rescue experiments, chronic cercosporamide treatment did not lead to a significant improvement in the rotarod (motor coordination) or novel object recognition tests in Fmr1<sup>1/y</sup> mice (Figures S6B and S6C). It also did not reverse the macroorchidism phenotype in Fmr1<sup>1/y</sup> mice (Figure S6D). These data constitute a pharmacological approach to selectively reduce eIF4E phosphorylation, and, in conjunction with the genetic rescue (Figure 4), bolster the important role of translational control through eIF4E phosphorylation in rescuing core ASD-like symptoms in Fmr1<sup>1/y</sup> mice.

### High-Dose Cercosporamide Impairs Social Approach Behavior in WT but Not Mmp9<sup>1/y</sup> Mice

We showed that translational control through phospho-eIF4E primarily controls a subset of mRNAs (Furic et al., 2010), and in the brain Mmp mRNAs are eIF4E key targets (Figures 3 and S3). Taking into account our finding that Mmp-9 overexpression in mice induced a subset of phenotypes similar to Fmr1 knockout mice (Figure 2), we hypothesized that Mmp-9, downstream of phospho-eIF4E is a cardinal effector of the Ras/MAPK/Mnk pathway in FXS (Figure 6A). To substantiate this claim, we used Mmp9<sup>1/y</sup> mice injected with 40 mg/kg cercosporamide (5 days). In contrast to Mmp9-Tg mice, Mmp9<sup>1/y</sup> mice do not display deficits in social interaction, as measured by the three-chamber social interaction test (Figure 6B). The 40 mg/kg cercosporamide dose impairs social approach behavior in WT mice, as evidenced by the significantly reduced interaction of the test mouse with the social stimulus, and the significantly reduced time spent in the social stimulus compartment, in the three-chamber test (Figure 6A). Remarkably, this dose had no significant effect on the social interaction of Mmp9<sup>1/y</sup> mice (Figure 6B). Taken together, these data show that the effects of cercosporamide are mediated through Mmp9.

### Recombinant Active MMP-9, but Not Pro-MMP-9, Abrogates the Rescue of Social Behavior Deficits by Cercosporamide in Fmr1<sup>1/y</sup> Mice

To further establish the role of Mmp9 in Fmr1<sup>1/y</sup> phenotypes, we used recombinant, active MMP-9, which exhibits a...
profound stimulatory effect on synaptic potentiation in CA1 (Bozdagi et al., 2007). A single dose (0.1 μg/μl, 2 μl) of active but not inactive pro- MMP-9 elicits an increase in potentiation in CA1 in vivo (Bozdagi et al., 2007). We postulated that proteolytically active MMP-9 infusion should occlude the rescue effects of chronic cercosporamide treatment in Fmr1−/− mice. To this end, we treated Fmr1−/− mice with the chronic cercosporamide dose (20 mg/kg) and simultaneously infused through canulas active or prorecombinant MMP-9 (two doses per day for 5 days, 0.1 μg/μl, 2 μl per dose). The mice were then tested in the preference for social novelty test. Infusion of active MMP-9 but not of the proform was sufficient to block the rescue effects of chronic cercosporamide treatment in Fmr1−/− mice, as demonstrated by the impaired preference for social novelty (Figure 6C).

These findings, together with the resistance of Mmp9−/− mice to high-dose cercosporamide (Figure 6B), demonstrate that translational control of Mmp9 mRNA through elf4E phosphorylation is a regulatory mechanism in Fmr1−/− mice, which could be dysregulated in FXS.

DISCUSSION

Here, we showed that FXS patients display an increase in MMP-9 protein and phospho-elf4E levels in the brain (Figure 1). Overexpression of MMP-9 in mice recapitulates major Fmr1−/− phenotypes (Figure 2). We also demonstrate that genetic inhibition of elf4E phosphorylation reduces Mmp9 mRNA translation (Figure 3). Likewise, genetic or pharmacological inhibition (cercosporamide) of phospho-elf4E rescues FXS-like phenotypes in Fmr1−/− mice (Figures 4 and 5). Thus, we postulate that a substantial fraction of the FXS-like phenotypes in Fmr1−/− mice can be explained by exaggerated phospho-elf4E-dependent Mmp9 mRNA translation.

Reversal of Exaggerated Translation in Fmr1−/− Mice by Phospho-elf4E Inhibition

A hallmark of Fmr1 deletion in mice is an increase in global protein synthesis, due to the absence of the translational “brake” that FMRP sets downstream of group 1 mGluRs (Bhattacharya et al., 2012; Huber et al., 2001; Osterweil et al., 2013; Udagawa et al., 2013). In Fmr1 knockout mice, mutation of the single phosphorylation site on elf4E or haploinsufficiency of Mnk1 and Mnk2 restored the general translation rates (Figure 3). However, translation was not restored for all FMRP mRNA targets. Restoring translation through normalizing elf4E phosphorylation primarily affected Mmps (Mmp9, Mmp2, Mmp3, Mmp7, and Mmp24) and Dig4 (PSD-95) (Figure S3), but not other FMRP targets such as Camk2a (CamKIIα), Shank3, or Map1b. This is similar to findings in Fmr1/S6K1 double-knockout mice, inasmuch as restoration of translation following ablation of S6K1 affects translation of most, but not all FMRP target mRNAs (Bhattacharya et al., 2012). Thus, it is likely that, downstream of group 1 mGluRs, different translation pathways such as 4E-BPs, S6Ks, and phospho-elf4E govern the translation of distinct pools of neuronal mRNAs.

Genetic or Pharmacological Inhibition of elf4E Phosphorylation Restores Core FXS Behaviors in Fmr1−/− Mice

Excessive Ras/Erk signaling was reported in FXS patients (Wang et al., 2012). We demonstrated increased phosphorylation of elf4E, which is a downstream target of the Ras/Erk signaling, along with increased expression of MMP-9 in post-mortem brain samples (Figure 1). These findings in conjunction with increased phosphorylation of elf4E in FXS patients lymphocytes (Hoeffer et al., 2012) and increased MMP-9 protein expression in amniotic fluid of ASD mothers (Abdallah et al., 2012) raise the possibility that phospho-elf4E regulation may be used to diagnose FXS or ASD at earlier ages. Alanine mutation of the phospho-Ser209 site in elf4E or deletion of one copy of Mnk1 and Mnk2 causes a reduction in elf4E phosphorylation (Figures 3 and 4). Similarly, using cercosporamide, a Mnk1/Mnk2 inhibitor, we were able, following chronic treatment, to reduce elf4E phosphorylation (Figure 5). In all cases, we achieved a rescue of the exaggerated protein synthesis, the enhanced mGluR-LTD (without affecting input/output and paired pulse ratio [Figures S5A and S5B]), the immature CA1 dendritic spine morphology, and the FXS-like behaviors (preference for social novelty, aspects of social interaction with juvenile males and females, light-dark transition, open-field exploration, and audiogenic seizures; Figures 4 and 5).

Figure 5. Pharmacological Inhibition of elf4E Phosphorylation Rescues FXS-like Phenotypes

(A) Cercosporamide (CERC.) is a selective potent inhibitor of Mnk1/Mnk2 and thus of phospho-elf4E.
(B) Western blot of hippocampal lysates from WT and Fmr1−/− mice injected with vehicle or treated chronically with cercosporamide (20 mg/kg). Representative immunoblots are shown, probed with antibodies against the indicated proteins; β-actin was the loading control.
(C) Quantification of western blots from (B); n = 3, phospho-elf4E protein amounts are normalized to elf4E and presented as percentage change relative to vehicle. *p < 0.05 Student’s t test.
(D and E) Fmr1−/− (Veh., n = 18; Cerc., n = 17) and WT (Veh., n = 14; Cerc., n = 10) mice were injected daily with cercosporamide (20 mg/kg) or vehicle for 5 consecutive days and 1 hr after the last injection hippocampal slices were prepared. Enhanced mGluR-LTD in Fmr1−/− slices was normalized after chronic treatment with cercosporamide. Scale bar, 5 ms and 1 mV. **p < 0.03, using one-way ANOVA followed by Bonferroni post hoc tests.
(F) Preference for social novelty three-chamber social interaction test, showing time spent in each chamber (LEFT) and time spent interacting with the novel social stimulus (right; stranger 2; S2) or the previously encountered mouse (stranger 1; S1); C, center compartment.
(G) Social interaction with a juvenile male mouse test. Latency to attack and time spent in affiliation are measured for the indicated genotypes.
(H) Social interaction with a female mouse test. Time engaged in self-grooming and time spent in affiliation are depicted.
(I) Light-dark transition test. Number of transitions between the light and dark compartments is shown.
(J) Open-field exploration. Number of entries and time spent in the center square of an open field is measured.
(K) Audiogenic seizure frequency (% of animals having seizures). X marks resistance of WT mice to AGS.

For (F)–(K), n = 12 for each group; ***p < 0.001, *p < 0.05, two-way ANOVA with Bonferroni’s post hoc. See also Figures S5 and 6. Data are presented as mean ± SEM (error bars).
Cercosporamide Selectively Inhibits eIF4E Phosphorylation and Reverses FXS-like Phenotypes

Our findings highlight cercosporamide as an inhibitor of eIF4E phosphorylation in the brain (Figure 5; Figures S5 and S6), which reverses a number of FXS-like phenotypes in adult Fmr1<sup>−/−</sup> mice. We showed that (1) a chronic subthreshold 20 mg/kg dose does not affect social behavior in WT, Mnk<sup>het</sup>, or Eif4e<sup>δ</sup> mice and (2) a chronic 40 mg/kg above-threshold dose impairs social interaction in WT mice, but not in Mnk<sup>het</sup> or Eif4e<sup>δ</sup> (Figure S5). These data indicate that our rescue experiments were carried out using a concentration range where cercosporamide does not have any off-target effects. Infusion of the active but not the latent form of recombinant MMP-9 abrogated the rescue effect of chronic cercosporamide injection in Fmr1<sup>−/−</sup> mice. Thus, cercosporamide blocks Mnk kinase activity and selectively inhibits Mmp9 translation through reduced phosphorylation of eIF4E. These data are consistent with previous work demonstrating that lovastatin, a drug prescribed for treatment of high cholesterol, inhibits Ras-ERK1/2 upstream of phospho-eIF4E, corrects excessive protein synthesis, and prevents epileptogenesis in Fmr1<sup>−/−</sup> mice (Osterweil et al., 2013).

**Figure 6. Mmp9 is a Critical Target of Phospho-eIF4E-Dependent Translation in Fmr1<sup>−/−</sup> Mice**

(A) Mmp9 is translationally controlled by phospho-eIF4E in FXS.

(B) Three-chamber social interaction test in WT or Mmp9<sup>−/−</sup> mice, injected with vehicle or a chronic (5 days), “above-threshold” dose of cercosporamide (CERC.; 40 mg/kg). Time spent in each chamber (left) and time spent sniffing each wire cage (right), are shown: S1, stranger 1 (social stimulus); C, center compartment; E, empty wire-cage compartment (nonsocial stimulus).

(C) Preference for social novelty three-chamber social interaction test in WT and Fmr1<sup>−/−</sup> vehicle or cercosporamide (20 mg/kg, 5 days) treated, and simultaneously infused with recombinant pro or active forms of Mmp9 (0.1 μg/ml, 2 μl per dose, two times a day for 5 days). Time spent in each chamber (LEFT) and time spent interacting with the novel social stimulus (right; stranger 2: S2) or the previously encountered mouse (stranger 1: S1); C, center compartment; i.c.v., intracerebroventricular infusion. For (B) and (C), n = 10 for each group; ***p < 0.001, *p < 0.05, two-way ANOVA with Bonferroni’s post hoc.

**eIF4E Phosphorylation and Mmp-9 Overexpression as a Potential Therapeutic Target in FXS/ASD, Downstream of Group 1 mGluRs/Ras/ERK/Mnk**

Increased amounts of Mmp-9 (Figure 2), but not deletion of Mmp9 (Figure 6), engender FXS/ASD-like phenotypes. The lack of social deficits in Mmp9<sup>−/−</sup> could be conceivably explained by homeostatic regulation of other members of the MMP family. Mice overexpressing Mmp-9 recapitulate several FXS-like phenotypes, indicating that Mmp-9 is responsible for a significant part of the Fmr1<sup>−/−</sup> phenotype (Figure 2), which is consistent with the increased translation of Mmp9 mRNA observed in Fmr1<sup>−/−</sup> mice (Figure 1). In particular, deletion of Mmp9 in Fmr1<sup>−/−</sup> mice, rescued synaptic, dendritic spine, and behavioral deficits, further supporting the notion that Mmp-9 is a master player in FXS phenotypes (Sidhu et al., 2014). Mmp-9 is a crucial target downstream of mGluRs/Mnk/phospho-eIF4E, because it remodels the extracellular matrix by proteolyzing some of its components, such as cell adhesion molecules, extracellular proteins, and potentially receptor subunits (Huntley, 2012). These
activities of MMP-9 may intersect with those of proteins implicated in ASD/FXS that are important for synaptic function and maturation. Thus, restoring normal Mmp9 translation impacts the regulation of several Mmp-9 targets, which are associated with FXS/ASD. Moreover, Mmp-9 is downstream of group 1 mGluRs, and it offers an appealing and selective avenue for treatment that would exclude off-target upstream effects.

**EXPERIMENTAL PROCEDURES**

**Knockin and Knockout Mice**

Eif4eki<sup>+/−</sup> (knockin Swr209Ala) mice were previously described (Furic et al., 2010). Fmr1<sup>−/−</sup>, Mmp9<sup>−/−</sup>, and Mnk1<sup>−/−</sup>/Mnk2<sup>−/−</sup> mice were on the C57B/6 background (Jackson Laboratories). All procedures were in compliance with the Canadian Council on Animal Care guidelines and were approved by McGill University, Université de Montréal, NCSR Demokritos Animal Care Committees and by the Eli Lilly and Company Institutional Animal Care and Use Committee.

**Polysome Profile Analysis and qRT-PCR**

Polysome profile analysis and qRT-PCR were carried out as described (Gkogkas et al., 2013).

**Western Blotting and Antibodies**

All tissues were dissociated in RIPA buffer (unless otherwise specified). Western blotting was previously described (Gkogkas et al., 2013).

**Three-Chamber Social Approach and Preference for Social Novelty Tests**

A three-chamber arena was used to assess social approach and preference for social novelty and was previously described (Gkogkas et al., 2013).

**Self-Grooming Test**

Mice were placed in a Plexiglas cage with fresh bedding and no nest or cardboard material. Self-grooming behavior was recorded for 10 min following an initial 10 min habituation phase.

**Social Interaction with Juvenile Male or Female Tests**

Experimental and stimulus mice (juvenile 4-week-old C57B/6 male or 12-week-old C57B/6 female) were habituated to the experimental room and the Plexiglas cage for 5 min. The unfamiliar stimulus mouse was then introduced into the testing cage and left there for 5 min. Aggression, interaction and affiliation, and self-grooming were scored.

**Light-Dark Transition Test**

The test apparatus was composed of two chambers: a dark enclosed chamber composed of wood (15 × 21 × 21 cm) and a larger chamber (30 × 21 × 21 cm) with three clear Plexiglas walls and an open top. The two chambers are connected by a small opening. Mice were placed into the “light” side and allowed to explore freely for 10 min. An entry was defined as the mouse placing all 4 ft into each zone.

**Open-Field Exploration**

Mice were placed into the center of a 40 × 30 cm chamber. Data were collected in 2 min intervals for each mouse for 30 min. The number of entries into the center square, which was used as a measure of anxiety-like behavior was calculated.

**Audionic Seizures**

The test apparatus consisted of a Plexiglas cylinder (40 cm diameter and 60 cm deep) covered by a plate with a 120 dB alarm as described in Musumeci et al. (2007).

**Analysis of Neuronal Morphology by Golgi-Cox Staining**

Rapid GolgiKit (FD NeuroTechnologies) was used for the staining procedure according to the manufacturer’s instructions as described in Gkogkas et al. (2013).

**Electrophysiology**

Electrophysiological experiments were performed as previously described (Knouottskey et al., 2013) with some modifications.

**Measurement of De Novo Protein Synthesis**

Transverse hippocampal slices (400 μm) were prepared from 5- to 6-week-old mice and allowed to recover for at least 3 hr. Puromycin labeling was performed as described previously (Hoefler et al., 2011; Bhattacharya et al., 2012) with some modifications.

**Statistical Analysis**

Experimenters were blinded to the genotype during testing and scoring. All data are presented as mean ± SEM (error bars). Statistical significance was set a priori at 0.05 (NS, nonsignificant). Details for tests used are provided in the figure legends and Supplemental Experimental Procedures.

**SUPPLEMENTAL INFORMATION**

Supplemental Information includes Supplemental Experimental Procedures and six figures and can be found with this article online at http://dx.doi.org/10.1016/j.celrep.2014.10.084.

**AUTHOR CONTRIBUTIONS**

C.G.G. and N.S. conceived, designed, and supervised the work. C.G.G. and A.K. designed, supervised, and carried out behavioral, electrophysiological, and biochemical experiments. R.C. and M.P.-K. carried out imaging experiments and edited the manuscript. S.M.J. carried out translational profiling experiments. N.G., A.K., A.F., and A.K.T. provided Mmp-9 transgenic mice, carried out spine imaging, and designed experiments. K.N. and T.J.P. helped with experimental design. B.W.K. and J.R.G. carried out cercosporamide experiments, edited the manuscript, and helped with experimental design. J.-C.L. supervised electrophysiology experiments and edited the manuscript. C.G.G., A.K., and N.S. wrote the manuscript.

**ACKNOWLEDGMENTS**

This work was supported by a CIHR operating grant to N.S. (MOP-114994) and J.-C.L. (MOP-125985), the Azrieli Foundation and Brain Canada team grant to N.S. and J.-C.L., the Fonds de la Recherche du Québec-Santé (grant to J.-C.L. FRQS; Groupe de Recherche sur le Système Nerveux Céntral), J.-C.L. is the recipient of the Canada Research Chair in Cellular and Molecular Neurophysiology. C.G.G. received support from the Wellcome Trust-University of Edinburgh Institutional Strategic Support Fund. Human tissue was obtained from the NICHD Brain and Tissue Bank for Developmental Disorders at the University of Maryland, Baltimore and the Harvard Brain Tissue Resource Center (grant number R24-MH 068855). We thank P. Hagerman and G. Espinal-Goyne for FXS postmortem brain samples and A. Sylvestre, S. Perreault, C. Lister, K. Gamache, and I. Harvey for technical assistance. J.R.G. and B.W.K. are employees of Eli Lilly and Company.
